# 1 Introduction

An operating system needs a *program scheduler* to schedule processes to run on the computer. There are three types of schedulers: long term, mid-term and short term. Moreover, an operating system uses two types of scheduling process executions which are preemptive and non-preemptive. In preemptive scheduling policy, a low priority process has to be suspended during its execution if a higher priority process is waiting in the same queue for its execution. In non-preemptive scheduling policy, processes are executed in first come first serve basis, which means the next process is executed only when the current running process finishes its execution.

There are a variety of ways to schedule processes that should run on the computer, called scheduling algorithms. These scheduling algorithms are: First Come First Serve (FCFS), Priority-based Scheduling, Shortest Job First (SJF), Longest Job First (LJF), Shortest Remaining Time First (SRTF), Highest Response Ratio Next and last but not least, the chosen topic of discussion: Round Robin (RR).

To measure the performance of the algorithms, there are two main variables are taken into account: *turnaround time* and *waiting time*, that are calculated based on each process's *arrival*, *burst* and *completion* time.

**Arrival time** is time at which the process arrives in the ready queue. Completion time is time at which process complete its execution.

**Completion time** is time at which process complete its execution.

**Burst time** is time required by a process for CPU execution.

To calculate *turnaround time* and *waiting time*, the following formulas are used:

$$TurnAroundTime = CompletionTime - ArrivalTime$$

$$WaitingTime = TurnAroundTime - BurstTime$$

## 2 Description, Advantages and Disadvantages

The Round Robin scheduling is simple, easy to implement, and starvation-free as all processes get fair share of CPU. It is particularly effective in a general-purpose time-sharing system or transaction processing system. It is also one of the most commonly used technique in CPU scheduling as a core.

The advantages of Round Robin scheduling is all the processes have the equal priority because of fixed time quantum. Starvation will never occur because each process in every Round Robin scheduling cycle will be schedule for a fixed time slice or time quantum.

The disadvantages of it is more overhead of context switching. In the Round Robin scheduling algorithm, as the time quantum decreases context switching increases. The increases in time quantum value results in time starvation which may put many processes on hold. If the time quantum decreases, it will affect the CPU efficiency. So, time quantum should neither be large nor small. If time quantum becomes infinity, Round Robin scheduling algorithm gradually become *First Come First Serve* (FCFS) scheduling algorithm.

### 3 Source Code

To understand the Round Robin scheduling algorithm, we have made a small command-line project written in *Java*.

The Java application takes in a list of processes and their respective *burst time* and *arrival time* that is keyed in by the user, and computes the order that processes should be executed in, by using the RR algorithm. Next, the program calculates the *turnarund time* and *waiting time* for each process and displays them in the standard output.

Firstly, we create a **Process** class which contains all the attributes of a process running on the computer. Using the object-oriented way, we can store an array of process objects later on in the main program. **Process.java** is as follows:

---

```
public class Process {

    private final int burstTime;
    private int remainingBurstTime, arrivalTime, timeArrivedInQueue,
        finishedTime;

    public Process(int burstTime, int arrivalTime) {
        this.burstTime = burstTime;
        this.remainingBurstTime = burstTime;
        this.arrivalTime = arrivalTime;
        this.finishedTime = 0;
    }

    public int getBurstTime() {
        return burstTime;
    }

    public int getRmBurstTime() {
        return remainingBurstTime;
    }

    public void setRmBurstTime(int burstTime) {
        this.remainingBurstTime = burstTime;
    }

    public void decreaseBurstTime(int quantum) {
        this.remainingBurstTime -= quantum;
    }
}
```

```
public int getArrivalTime() {
    return arrivalTime;
}

public void setArrivalTime(int arrivalTime) {
    this.arrivalTime = arrivalTime;
}

public void setTimeArrivedInQueue(int t) {
    timeArrivedInQueue = t;
}

public void setFinishedTime(int finishedTime) {
    // only set the completion time if it's not already been set
    if (this.finishedTime == 0) {
        this.finishedTime = finishedTime;
    }
}

public int getTurnaroundTime() {
    // Using the formula
    return (int) Math.abs(finishedTime - timeArrivedInQueue);
}

public int getWaitingTime() {
    // Using the formula
    return getTurnaroundTime() - burstTime;
}
}
```

---

## 4 Output and Discussion

Present the outputs here.

## 5 Conclusion

Summarize your work.
